Parasitic Copepod (*Lernaea cyprinacea*) Outbreaks in Foothill Yellow-legged Frogs (*Rana boylii*) Linked to Unusually Warm Summers and Amphibian Malformations in Northern California

Sarah J. Kupferberg[1,2], Alessandro Catenazzi[2], Kevin Lunde[3], Amy J. Lind[4], and Wendy J. Palen[5]

How climate change may affect parasite–host assemblages and emerging infectious diseases is an important question in amphibian decline research. We present data supporting a link between periods of unusually warm summer water temperatures during 2006 and 2008 in a northern California river, outbreaks of the parasitic copepod *Lernaea cyprinacea*, and malformations in tadpoles and young of the year Foothill Yellow-legged Frogs (*Rana boylii*). Relative to baseline data gathered since 1989, both 2006 and 2008 had significantly longer periods when daily mean water temperatures exceeded 20°C compared to years without copepod outbreaks. Infestation varied spatially in the watershed, as prevalence increased concomitantly with temperature along a 5.2 km longitudinal transect. At breeding sites of *R. boylii* with copepods in 2006, infestation ranged from 2.9% of individuals upstream to 58.3% downstream. In 2008, copepods were absent from the most upstream sites and infested up to 28.6% of individuals sampled at downstream locations. Copepods most frequently embedded near a hind limb or the cloaca. Among individuals with parasites in 2006, 26.5% had morphological abnormalities compared to 1.1% of un-infested individuals. In 2008 when the infestation peak occurred late in development (post Gosner stage 39), abnormalities were not associated with copepod infestation. In both years, recently metamorphosed frogs with copepods were, on average, slightly smaller than those not infested. These occurrences represent a sudden increase in local prevalence atypical for this river ecosystem. Previously we had only once seen copepods on amphibians (on non-native Bullfrogs, *Rana catesbeiana*), six km further downstream. Pacific Chorus Frogs, *Pseudacris regilla*, which co-occur with *R. boylii* in shallow near shore habitats were not used as hosts. The data suggest that increasing summer water temperatures, decreased daily discharge, or a combination of both, promote outbreaks of this non-native parasite on an indigenous host, and could present a threat to the long-term conservation of *R. boylii* under the flow regime scenarios predicted by climate change models.

WITH increased attention on parasitism and disease as threats to biodiversity, there is a need to identify the pathogens and parasites which pose significant risks (Daszak et al., 2000; Smith et al., 2006) and determine which ecological factors may be drivers of disease spread (Plowright et al., 2008). Warming and changes in precipitation anticipated with global climate change are predicted to exacerbate the impact of parasites and pathogens in aquatic ecosystems (Marcogliese, 2001). Increased air and water temperatures can enhance the breeding of vector organisms (Freed et al., 2005), increase overall population growth rates of a pathogen (Woodhams et al., 2008) or accelerate transmission rates by causing proliferation of infective stages (Freed et al., 2005; Poulin, 2006). Amphibians with narrow thermal niches are particularly at risk from warming, and are vulnerable to multiple stressors including the spread of virulent infectious diseases, such as chytridiomycosis (Berger et al., 1998; Muths et al., 2003; Scherer et al., 2005; Wake and Vredenburg, 2008), which may be expanding through space and time independent of warming (Lips et al., 2008). The role of pathogens and parasites in amphibian declines, however, is not limited to chytridiomycosis (Pessier, 2002; DiRosa et al., 2007; Picco and Collins, 2008), and as Pounds et al. (2007) state, "the rogues' gallery of amphibian pathogens that benefit from climate change is only just beginning to be assembled."

Accordingly, our intention in this paper is to alert biologists to a crustacean parasite particularly sensitive to temperature. We report the prevalence of a copepod, *Lernaea cyprinacea*, affecting larval (Fig. 1A, B) and recent post-metamorphic stages (Fig. 1C, D) of the river breeding Foothill Yellow-legged Frog, *Rana boylii*. We hypothesize that the outbreaks associated with warm and dry conditions in the South Fork Eel River of northern California foreshadow a consequence of the climate change predictions across the range of *R. boylii* in California and Oregon. Stream temperatures will likely be influenced through increased ambient summer air temperatures and reduced discharges (Kiparsky and Gleick, 2003; Snyder et al., 2004; Webb et al., 2008), two factors that control the heating of water as it flows downstream. General sensitivity analyses of a process-based, basin-scale stream temperature model developed for the South Fork Eel indicate that reductions in flow may have the greatest impacts on stream temperature (Allen, 2008).

Lernaea cyprinacea, commonly referred to as Anchor Worm, is a Eurasian species that has become globally widespread. Despite its Latin name, it does not limit itself to cyprinid fishes for hosts. There are several reports, both historical and recent, of *L. cyprinacea* using amphibians as hosts in North America (Haderlie, 1950; Baldauf, 1961; Tidd, 1962; Hoffman, 1967), South America (Martins and Souza, 1996; Alcalde and Batistoni, 2005), and Asia (Ming, 2001).

Fig. 1. (A) Adult female copepod parasite (approx. 7 mm long) *Lernaea cyprinacea* on a tadpole of *Rana boylii* with arrow indicating the insertion site near the base of a developing hind limb. (B) A close-up view of the copepod's abdomen with arrow indicating its egg sacs. Copepods on recently metamorphosed frogs embedded on the throat (C) and near the cloaca (D).

Parasitism by *L. cyprinacea* is generally a problem in aquaculture facilities and in the aquarium trade (Hoffman, 1999), where infestation can be potentially lethal or pathogenic when secondary microbial infections occur at the sites of lesions. Parasitism by *L. cyprinacea* can, however, be a wildlife conservation issue because of its negative effects on the condition of sensitive native fish (Durham et al., 2002; Bond, 2004; Hoffnagle et al., 2006) and possibly amphibians (Ming, 2001) when it becomes established in the wild.

There are approximately 10,000 species (in 187 families) in the Copepoda subclass of Crustacea, and almost half of these species are either parasitic or live in association with other aquatic animals (Bowman and Abele, 1982; Huys and Boxhall, 1991). Like most parasitic copepods, *L. cyprinacea* has a direct life cycle involving only one host, and transmission occurs via free swimming nauplii and the first copepodid larval stage. Adult females carry their eggs in sacs outside their body (Fig. 1B), from which they release nauplii. *Lernaea cyprinacea* is highly thermophilic (Marcogliese, 1991) and can develop from mature eggs to the first parasitic stage in as little as 4–8 days (Al-Hamed and Hermiz, 1973). The first larval stage is taken up by fish in the gills or by a tadpole through the spiracle (Bird, 1968). The first through fifth copepodid stages are localized within the tadpole's mouth and branchial chambers (Shields and Tidd, 1963). Copepodids attach by their maxillipeds and remain sessile, eating epithelial tissue and underlying connective tissue (Shields and Tidd, 1974) until the fifth larval stage when copulation occurs. Post-copulation, females undergo another molt, travel along the integument of the tadpole, and penetrate the tadpole's tissue with their heads. A transformation then occurs in which the body of *L. cyprinacea* lengthens (up to approx. 1 cm) and the cephalothorax develops into an anchor shaped process (Bird, 1968).

Penetration sites can be anywhere, but most often near the juncture between tail and body, and a number of tadpole tissues (e.g., liver, lung, spinal cord) can be damaged (Tidd, 1962). As much of this previous work examining copepod effects on tadpoles has been conducted in the laboratory, our focus here is to document the *in situ* environmental conditions associated with parasitic copepod outbreaks, spatial patterns of prevalence, and the coincidence between the presence of copepods and morphological abnormalities in an otherwise robust population of frogs.

MATERIALS AND METHODS

We conducted parasite surveys along 5.2 km of the South Fork Eel River (SF Eel) on the University of California's Angelo Coast Range Reserve, Mendocino Co., California (39.733°N, 123.65°W). Study of *R. boylii* began there in 1989 with ongoing full-reach censuses of frog breeding established in 1992. Along the study reach, there are five perennial tributaries, and several more ephemeral drainages, inhabited by juvenile and adult *R. boylii*. Spawning, however, occurs only at historic breeding sites along the margins of the SF Eel. The sites are geomorphologically distinct locations (i.e., depositional areas, such as cobble bars or pool tail outs) with the most populous sites clustered near (within one riffle-pool sequence) tributary confluences (Kupferberg, 1996). Mean (±1 s.e.) inter-site distance is 118.8 ± 11.4 m (*n* = 44). The extent of individual movement among sites is not known, but we assume the collection of frogs using these breeding sites constitutes a meta-population.

We sampled frogs for copepods in 10% of the study reach (approximately 520 m) during 2006 and 2008. No copepods were observed on frogs in 2007. In 2006, search efforts were spatially concentrated and in 2008, search efforts were

spatially dispersed, but we sampled similar total lengths of river each year. On 17–18 August 2006, we visited the near-shore habitats of three breeding sites, at the upstream, midpoint, and downstream extent of the reach. One month later, as part of a mark and recapture demographic study, juvenile *R. boylii* were captured over three days, 16, 17, and 21 September, along a 460 m segment near the midpoint of the 5.2 km reach. Captured individuals received daily batch marks using Visible Implant Elastomer (Northwest Marine Technologies, Seattle, WA). To determine what proportion of the population was examined for copepods, we estimated the abundance of recently metamorphosed frogs for the three-day survey period using program CAPTURE (Otis et al., 1978; White et al., 1982). An estimator was not available for the best-fit model, so the model with the next highest ranking was used. Between 13 August and 7 September 2008, we visited 13 breeding sites. The relationship between parasite prevalence and distance was evaluated using linear regression. Prevalence data from 2008 were transformed by taking the arcsin square root of the proportion infested at each of the 13 breeding sites sampled. In both years we measured tadpole and frog snout-to-urostyle length (SUL) to the nearest mm, and visually inspected for ectoparasites and morphological abnormalities. In 2008, we also inspected Pacific Chorus Frogs, *Pseudacris regilla*.

To describe environmental conditions in the river, we calculated mean daily discharge (m^3 sec^{-1}) for August, and the number of summer days with mean water temperature $\geq 20°C$ from data collected hourly at the most upstream extent of the study reach. Stream gaging and thermal monitoring began in 1989 at a retired USGS gaging station re-established by M. E. Power and W. Dietrich. Not all years have complete data sets due to occasional equipment failures. The gaging station defines the starting point of the 5.2 km study reach where breeding censuses and parasite surveys occurred. Along with the abiotic factors, we calculated annual density of clutches of eggs (#/km) and compared values for 2006 and 2008 to the longer term means of ''no copepod'' years (1992–2005, 2007) using t-tests. To detect whether a gradient in water temperature exists along the length of the study reach, we placed iButton (Maxim Integrated Products, Sunnyvale, CA) temperature recorders at seven locations, between 25 August and 7 September 2008. Temperature was measured in 0.5°C increments every two hours, with an accuracy of ± 1°C. We calculated the two-week average of daily mean temperature and assessed the relationship with distance downstream using linear regression.

We investigated whether copepod infestation could be associated with the occurrence of abnormalities. For 370 individuals sampled in 2006 (332 were post-metamorphosis) and 411 in 2008 (159 were post-metamorphosis), we compared the frequency of abnormalities among animals infested by *L. cyprinacea* to the frequency of abnormalities in un-infested animals with G-tests of independence. We did not confirm the designation of ''un-infested'' by dissection or other independent method. Parasites may have been shed prior to our observations. Host rejection of *L. cyprinacea* by tadpoles of *R. pipiens* has been observed via a process involving extensive formation of connective tissue to encapsulate the anchor process of the copepod (Shields and Goode, 1978).

In 2008, we inspected abnormal *R. boylii* for trematodes, along with a random subset of normal individuals to determine if the parasite *Ribeiroia ondatrae* might be

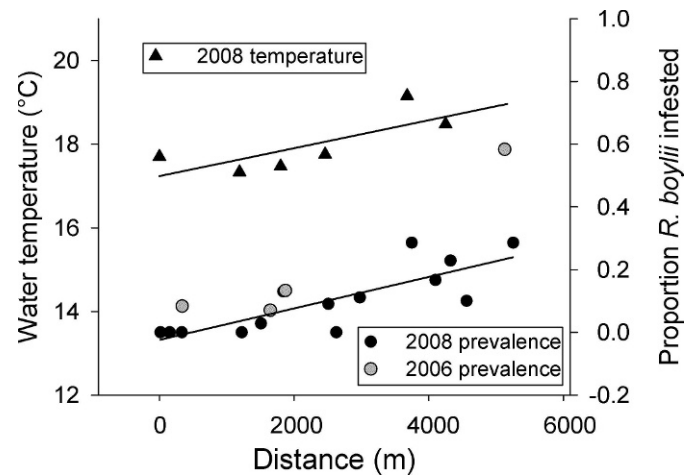

Fig. 2. Prevalence of parasitic copepod infestation in 2006 and 2008, and daily mean water temperature over 14 days between August and September 2008 along 5.2 km of the South Fork Eel River, Mendocino Co., California. For distance sampled, zero is at the most upstream end of the study reach.

associated with the observed malformations. However, due to the protected status of *R. boylii* in California, collections were limited. To reliably conclude the presence and abundance of trematodes, we supplemented necropsy data of *R. boylii* with dissections of normal and abnormal *P. regilla* that had developed in the same reach of the SF Eel. *Pseudacris regilla* is present at breeding sites of *R. boylii*, does not have any special protections, and is susceptible to infection by *R. ondatrae* (Johnson et al., 1999). Groups of 7–8 metamorphs of *P. regilla* were collected at two-week intervals during August and September 2008. Following euthanasia in MS-222, frogs were inspected for all trematode metacercariae using a stereo dissection scope. Metacercariae were counted, removed, excysted, and identified using a compound microscope.

RESULTS

The overall prevalence (# of infested individuals/total # inspected) of copepod infestation on *R. boylii* was 9.2% (34 cases/370 individuals in 520 m) in 2006, and 10.5% (43/411 individuals) in 2008. None of 75 inspected *P. regilla* had copepods. Copepod prevalence varied spatially (range 7.0 to 58.3% in 2006, 0 to 28.6% in 2008), and the angular transformed proportion of infested individuals increased significantly with distance downstream along the 5.2 km of river sampled ($R^2 = 0.68$, $F = 23.05$, df = 1,12, $P < 0.001$; Fig. 2). Daily mean water temperature similarly increased with distance ($R^2 = 0.70$, $F = 11.7$, df = 1,6, $P = 0.02$; Fig. 2).

The population estimate, based on the 2006 mark and recapture effort, was 622 ± 24.3 recently metamorphosed frogs, which corresponds to a density of 1.35 ± 0.05 individuals per m of river. Our capture rates of 0.73 and 0.78 frogs per m in 2006 and 2008, respectively, indicate that we were inspecting about half the animals present at our sampling sites, assuming similar densities between years.

The outbreaks of copepods were associated with three unusual conditions: high water temperature (in 2006 and 2008); drought induced low flow (2008); and high densities of tadpoles (Fig. 3). In 2006, *R. boylii* had the greatest reproductive output in 17 years of record, with the number
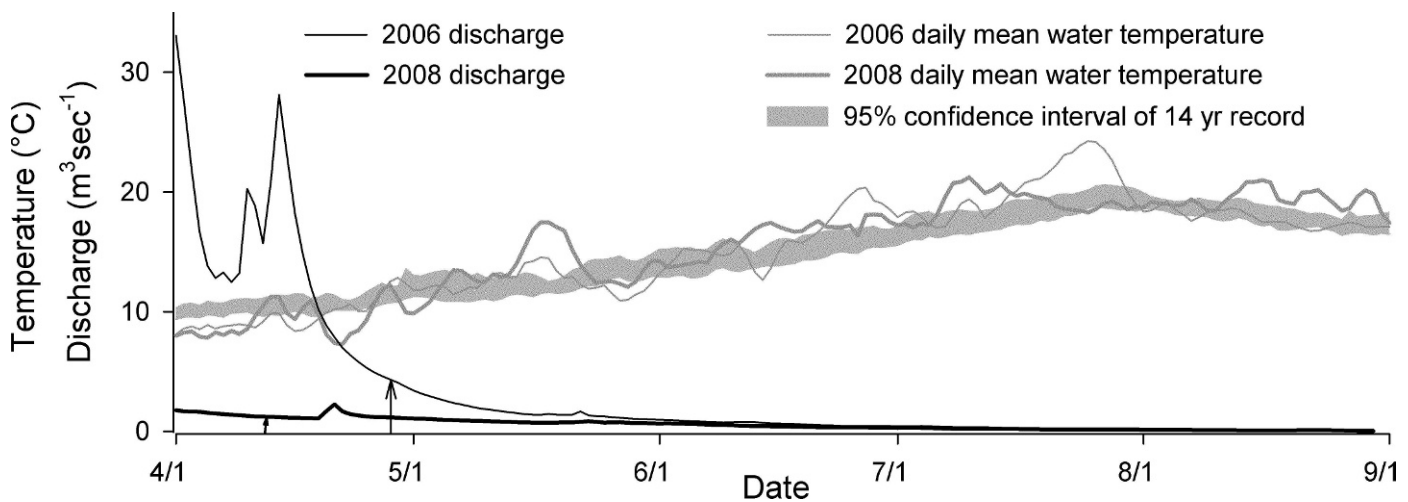

Fig. 3. Daily mean water temperature and flow conditions during the summers of 2006 and 2008 when outbreaks of *Lernaea cyprinacea* occurred. Confidence interval (shaded gray area) is based on the distribution of temperatures for that date over 14 years with complete records (1990–1998, 2001, 2003–2005, 2007) when copepods were not observed on amphibians. Arrows indicate the discharge when frogs began breeding (earlier in 2008, later in 2006).

of clutches deposited in the study reach significantly greater than average (Table 1). Additionally, there were significantly more days when the mean daily water temperature was above 20°C in 2006 and 2008, compared to years without copepod outbreaks (14 years with complete temperature data sets: 1990–1998, 2001, 2003–2005 and 2007). In 2008, reproductive output was again high, and extremely low flow conditions contributed to high concentrations of tadpoles in near shore habitats.

The abundance (# of parasites/host) was uniformly a single embedded copepod in 2008. In 2006, only three individuals had two copepods, with the remainder having a single parasite. Copepod prevalence differed among Gosner stages in infested tadpoles and froglets in both 2006 (G = 13.85, df = 2, *P* = 0.001) and 2008 (G = 7.79, df = 1, *P* = 0.05). The highest prevalence in 2006 occurred at earlier Gosner stages than in 2008 (Fig. 4A). Copepods were most frequently embedded near the base of a hind limb or the cloaca (Fig. 4B). Morphological abnormalities were also most frequent in the hind limbs (Table 2), but were not generally common in the whole sample of *R. boylii* (3.42% in 2006, and 2.68% in 2008). Of those infested with copepods in 2006, 26.5% had abnormalities while only 1.1% of un-infested animals had abnormalities. The association between limb abnormalities and copepod infestation was highly significant (G = 30.4, df = 1, *P* < 0.001). In 2008, however, no association was observed (G = 0.8, df = 1, *P* > 0.5). We also found un-infested *P. regilla* missing a hindlimb (one case each in 2006 and 2008) and

infested, but morphologically normal, Pacific Giant Salamander (*Dicamptodon ensatus*): one dead in 2006, one alive in 2007.

In both years recently metamorphosed frogs with copepods were slightly smaller than those without copepods embedded (Fig. 4C). These differences approach statistical significance (*F* = 3.02 2, df = 1, 485, *P* = 0.08) in a two-way analysis of variance of ln(SUL). Differences in size at metamorphosis were significant between years (*F* = 10.97, df = 1, 485, *P* = 0.001), and there was no copepod × year interaction (*F* = 0.07, df = 1, 485, *P* = 0.8).

The community of trematode parasites observed in 14 *R. boylii* and 26 *P. regilla* recent metamorphs is summarized in Table 3. *Ribeiroia ondatrae* was identified in only one of the *R. boylii* and was absent in all *P. regilla*. The one infected *R. boylii* had a single metacercarial cyst, and had normal morphology. Echinostomes were common in the kidneys of both species, though four times more abundant in *R. boylii* (*P* < 0.01). *Echinostoma* sp. infection intensity was quite variable; for example, two *R. boylii* suffered a burden of more than 700 cysts while others had none. *Manodistomum* sp. was significantly more abundant in *P. regilla* metamorphs (*P* < 0.05). Other larval trematodes known to infect amphibian larvae, e.g., *Fibricola* sp., *Alaria* sp., *Clinostomum* sp., *Auridistomum* sp. (Sutherland, 2005), were not encountered. In the field, while inspecting for copepods, we observed the monogenean trematode, *Gyrodactylus* sp., on the tails of many tadpoles of *R. boylii*.

Table 1. Environmental Conditions Associated with Outbreaks of Parasitic Copepods on *Rana boylii* (2006 and 2008), as Well as Summers When Copepods Were Not Observed. Asterisks indicate the significance of one-sample t-tests comparing the mean of non-copepod years to the 2006 and 2008 individual values, using the Bonferroni adjusted (for six tests) critical value of *P* < 0.0083.

| Environmental factor n = # of years	years w/o copepods (mean ± s.e.)	2006	2008
No. days mean water temperature > 20°C (*n* = 14)	8.57 ± 2.3	16*	15*
Mean daily discharge for August (m³ sec⁻¹, *n* = 18)	0.168 ± 0.018	0.195	0.110*
R. boylii density (clutches/km, *n* = 15)	100.3 ± 6.5	176.9*	134.0*

Fig. 4. Prevalence of infestation by *Lernaea cyprinacea* (A), insertion points (B), and snout–urostyle length (SUL) of Gosner stage 46 individuals (C), among tadpoles of *Rana boylii* in 2006 (dark bars) and 2008 (light bars). Numbers above bars indicate total number of individuals examined.

DISCUSSION

The outbreak of *L. cyprinacea* in the SF Eel was associated with periods of warm water temperatures, declining discharge, and shrinking pool sizes, conditions which are typical for infestations on fish in other rivers (Adams, 1984; Medeiros and Maltchik, 1999). In addition to the warm water temperatures, host density was high because there were record high numbers of egg masses of *R. boylii* and conditions for survival to hatching were excellent. The two main sources of embryonic mortality, scour and stranding (Kupferberg, 1996), were largely absent as there were no spates sufficient to scour egg masses and river stage declined gradually to keep eggs inundated. In late July 2006, there was an abnormally hot period when fish kills were observed. In 2008, there were also several warm periods when mean daily water temperatures exceeded the upper bounds of the 95% confidence interval for the mean of that date, although not as extreme as in 2006. We hypothesize that tadpoles may have been both directly stressed by periods of high temperatures and indirectly affected because warmth favors the development, reproduction, and fecundity of *L. cyprinacea* (Shields, 1978). Extremely low discharge and concomitantly slow current velocities in the river may also have enhanced transmission of copepod nauplii, as has been observed for the free-swimming stages of the myxozoan parasite responsible for whirling disease in salmonids (Hallett and Bartholomew, 2008).

The spatial pattern of higher copepod prevalence at the downstream end of the study reach may indicate an invasion front as well as reflect the gradient in thermal conditions (i.e., cooler water upstream). We observed these parasites 14 years earlier (21 September 1992) on non-native amphibians six km downstream of the study reach. In a pool with dense aggregations of first year Bullfrog tadpoles (*R. catesbeiana*), five tadpoles with *L. cyprinacea* embedded at the hind limb buds were collected and identified via dissection (M. Poteet and Kupferberg, unpubl.). Adult copepods were not seen on amphibians in the intervening years despite

Table 2. Relative Frequency of Abnormality Types in Tadpoles and Metamorphs of *Rana boylii* (Total Individuals Examined: *n* = 370 in 2006, 411 in 2008).

		n

Table 3. Trematode Parasite Community within *Rana boylii* and *Pseudacris regilla* from the South Fork Eel River. Sample size (*n*) is number of amphibians inspected via necropsy (collected between 15 August and 15 September 2008). The first number is infection prevalence (# infected frogs/# inspected frogs), while the number in parenthesis is parasite abundance (mean # metacercarial cysts per inspected frog). Listed *P*-value of non-parametric Wilcoxon rank-sum test compares trematode abundance between the two species.

Type of trematode	*Rana boylii* (*n* = 14)	*Pseudacris regilla* (*n* = 26)	*P*
Ribeiroia ondatrae	7.1% (1)	0%	n.s.
Echinostoma spp.	100% (222.8)	84.6% (49.6)	0.004
Manodistomum spp.	57.1% (6.5)	92.3% (10.7)	0.040
Unidentifiable cyst	7.1% (1)	3.8% (1)	

active use of the Angelo Coast Range Reserve by ecologists. As noted during annual fish snorkeling surveys (begun in 1988 by M. E. Power, pers. comm.), however, copepods have been continuously present on Roach (*Lavinia symmetricus*), and in 2006 and 2008 were abundant on juvenile Steelhead (*Oncorhynchus mykiss*) as well as Roach (Palen, pers. obs.).

It is possible, that during the intervening years larval *L. cyprinacea* have been present in tadpole gills, but inconspicuous to field researchers. In years with 'normal' temperatures, *R. boylii* might rid themselves of the ectoparasitic copepodids in the branchial chamber if gill resorption preceded *L. cyprinacea* reaching sexual maturity and transforming to mesoparasitic embedding adults. This hypothesis is supported by observations of 15 tadpoles collected in 2006 and held in captivity as part of a swimming study (Kupferberg et al., 2008). Tadpoles maintained for one week at 18°C with several water changes did not reveal any parasites when examined at 5–10× magnification. After completing swimming trials, four of 15 SF Eel tadpoles transferred to a warmer facility (21–23°C) had adult parasites embedded near a hind limb within three days. Tadpoles from two other rivers did not develop infestations. After removing the infested individuals and chilling the water ≤19°C, no further incidences of copepods embedding occurred and all 11 tadpoles successfully metamorphosed. Of the four with copepods, two survived. One could not bend its left hind limb and died six weeks post-metamorphosis. The other lacked visible abnormalities but was small and died three months later. This trend of infested frogs being smaller was consistent in the wild at the SF Eel, and likely has negative consequences as size at metamorphosis is a correlate of over-winter survival and fitness in amphibians (Smith, 1987; Semlitsch et al., 1988; Altwegg and Reyer, 2003).

We have not established a cause and effect relationship between the growth of a copepod's anchor process and malformation of a limb, although insertion is most common near the hind limb (Tidd, 1962; Shields and Tidd, 1963), and copepods have previously been suspected to play a role in hind limb abnormalities (Ming, 2001). The predominance of inguinal attachment is consistent with a fluid dynamics model illustrating that the region is a dead zone in flow around a tadpole's body where hind limbs can grow without increasing drag forces (Liu et al., 1996, 1997). High-speed videography observations confirm that echinostomatoid cercaria attack tadpoles in that region (Taylor et al., 2004) even while tadpoles twist, turn, and swim. Despite the propensity to embed near hind limbs, almost three-fourths of infested *R. boylii* in 2006 did not exhibit abnormalities and the association did not recur in 2008. We do not suspect widespread involvement of the trematode parasite *Ribeiroia ondatrae* at the SF Eel, but cannot eliminate it as a possibility.

One *R. boylii* was found with a cyst in 2008; however, that individual was morphologically normal. The absence in *P. regilla* also indicates that *Ribeiroia* is not common at the SF Eel. Infection by *Ribeiroia* can lead to severe limb malformations (Johnson et al., 1999, 2002; Johnson and Sutherland, 2003; but see discussion in Lannoo, 2008 for a critical review) with likely mechanisms including limb bud rotation when metacercariae encyst (Sessions, 1999; Stopper et al., 2002). Although *Ribeiroia* has been shown through laboratory and field studies to induce fore- and hind limb malformations (reviewed by Blaustein and Johnson, 2003), its absence at wetlands with high prevalence (>5%) of malformations is clear evidence that other causes are important factors (Meteyer et al., 2000; Lannoo et al., 2003; Skelly et al., 2007, Lannoo, 2008).

Other possible causes include the direct effects of heat stress on the development of hind limb abnormalities (Dournan et al., 1998) and asymmetries (Alford et al., 2007). Although the etiology of the abnormalities we observed is not known, we can rule out a wide range of anthropogenic factors that have been implicated in causing abnormalities, ranging from acidification, radioactive pollution, heavy metals, and agricultural chemicals (reviewed by Oullet, 2000; Lannoo et al., 2003; Lannoo, 2008). Surface and ground water pollutants are not likely in the remote and relatively pristine mixed-conifer forests within the Angelo Coast Range Reserve. Downwind drift of aerial pesticides is unlikely given the site's close proximity to the Pacific Ocean and prevailing wind direction from the northwest. Also, the <3% overall limb abnormality prevalence is still within an overall baseline of 0–3% and thus might not represent any deviation from normal genetic or developmental errors and injury.

A possible explanation for the lack of consistent association between copepods and abnormalities is that the parasite's effects may be stage specific. Experiments with tadpoles of *Rana pipiens* and *Ribeiroia ondatrae* illustrate that timing of infection can alter malformation outcomes (Schotthoefer et al., 2003). Tadpoles were exposed to cercariae at the pre-limb-bud (Gosner stages 24 and 25), limb-bud (Gosner stages 27 and 28), or paddle (Gosner stages 31–33) stages of development. At metamorphosis, only tadpoles infected at the limb-bud stage displayed a high (16%) malformation rate, whereas less developed tadpoles suffered significant mortality. When cercariae encysted after the paddle stage, neither limb development nor tadpole survival was influenced. At the SF Eel in 2008, tadpole breeding began more than two weeks earlier than in 2006, and warm temperatures in May accelerated development, such that many tadpoles' limbs had already completed formation at the peak of the copepod outbreak in August. In 2006, infestation was more prevalent in earlier develop-

mental stages relative to 2008. The better body condition (i.e., larger size) in 2008 may also have contributed to a different response to infestation. An explicit investigation of the relationship between the timing and location of an adult female copepod's penetration site, the condition of the tadpole host, and the potential teratogenetic effects on limb formation is needed.

Parasites are but one of many threats to *R. boylii*, which has disappeared from 54% of its historic sites (Davidson et al., 2002; Lind, 2005). Potential causes for decline are diverse, but absence from historic localities is more common in close proximity to large dams (Lind, 2005). Dam-associated risk factors to this species, whose entire life cycle is completed in fluvial habitats, include the scouring of egg masses by large magnitude dam releases (Lind et al., 1996) and predation by invasive species that flourish in waterways subject to flow diversion and regulation (Hayes and Jennings, 1988; Moyle and Light, 1996; Marchetti et al., 2004). Dams can also alter downstream thermal regime, but the extent of impacts on *R. boylii* has not been quantified, and whether dams would increase the risk of parasite outbreaks is not clear. Temperatures can be either raised or lowered during dam operation. When outfalls are at low elevation on a dam, water is drawn from the hypolimnion of the upstream reservoir, and the resulting temperatures downstream are often colder than they would be naturally and thus create a refuge from thermophilic parasites (Hoffnagle et al., 2006). Alternatively, the retention of water behind a dam can result in artificially low summer base flow discharges, causing unnaturally warm downstream temperatures. Stressors may also originate outside a population's watershed, such as the downwind drift of organophosphate pesticides (Davidson, 2004; Sparling and Fellers, 2007). At present, however, observations within regulated watersheds and manipulative field experiments implicate the direct effects of flow alteration, particularly aseasonal pulsed releases of water, as a proximal cause of *R. boylii* decline (Kupferberg et al., 2008). If copepod parasitism or the direct effect of thermal stress on *R. boylii* at the un-regulated SF Eel did result in low recruitment, we would not detect a population-level response until the females of the 2006 and 2008 cohorts reach reproductive maturity and their egg masses are counted in future censuses. Thus, the conservation implications of the parasites reported here remain an open question and an active area of research within our group.
